

# Error Correcting Codes

why? noisy channels

model: sending bits over a channel  
probability  $p$  that any bit flips.

Basic Example: message 1 bit.

message  $\xrightarrow{\text{encoding}}$  codeword

|   |     |
|---|-----|
| 0 | 000 |
| 1 | 111 |

this code  $\begin{cases} \text{detect 2 errors} \\ \text{correct 1 error (majority rules)} \end{cases}$

detect = know it isn't a codeword  
(not how many / where errors)

Eg. suppose send 000

| <u>received</u> | <u># errors</u> | <u>detected?</u> | <u>decoded</u>     |
|-----------------|-----------------|------------------|--------------------|
| 000             | 0               |                  | <div>000</div>     |
| 001             | 1               | <div>✓</div>     | <div>000</div>     |
| 010             |                 |                  |                    |
| 100             |                 |                  |                    |
| 110             | 2               | <div>✓</div>     | 111<br>(incorrect) |
| 011             |                 |                  |                    |
| 101             |                 |                  |                    |
| 111             | 3               | <div>✗</div>     | 111<br>(incorrect) |

Probability of correctly decoding

$p$  = prob for each bit that an error occurs

$$(1-p)^3 + p(1-p)^2 + (1-p)p(1-p) + (1-p)^2 p$$

prob. of no errors      error in 1st bit      error in 2nd      error in 3rd

If  $p = 0.1$ , this is 0.972.

---

Parity Check Code

message: 7 bits

encoded message: orig. message + 1 parity bit  
 $= \sum \text{of other bits mod } 2$

eg. 0110001  
→ 01100011

code =  $\{ 8 \text{ bit strings} : \sum \text{bits} = 0 \bmod 2 \}$  (even # of 1's)  
= set of codewords

Can detect 1 error (2 bits  $\rightarrow$  not detected)  
correct 0 errors.

Fundamental Trade-Off:

space (how long are codewords compared to message)

vs.

robustness (correcting & detecting more errors)

Def<sup>n</sup>. Let  $A$  be an alphabet (usually  $A = \{0, 1\}$ ).

$A^n$  =  $n$ -tuples of letters from  $A$  ie. strings

A code of length  $n$  is a non-empty subset of  $A^n$ .

The elements of the code are called codewords.

If  $|A| = 2$  then "binary code"

If  $|A| = 3$  then "ternary code"

If  $|A| = q$  then " $q$ -ary code"

Basic example

000, 111

$A = \{0, 1\}$

code =  $\{(0, 0, 0), (1, 1, 1)\}$

length 3 binary code w/ 2  
codewords

Checksum code

$A = \{0, 1\}$

code =  $\{8 \text{ bit strings w/ } \sum = 0 \pmod{2}\}$   
 $\subseteq A^8$

length 8 binary code  
w/  $2^7$  codewords

Def<sup>n</sup>. Let  $u, v \in A^n$   
The Hamming distance  $d(u, v) = \#$  of positions at which  $u$  &  $v$  differ.

eg.  $u = \begin{array}{|c|c|c|c|c|c|} \hline 0 & 1 & 0 & 0 & 1 & 0 \\ \hline \end{array}$   
 $v = \begin{array}{|c|c|c|c|c|c|} \hline 1 & 0 & 0 & 1 & 0 & 0 \\ \hline \end{array}$   
 $d(u, v) = 4$

Typically, decoding is done by choosing the nearest codeword in Hamming distance. "Nearest neighbour decoding"

Properties:  
(of H. dist.)

- 1)  $d(u, v) \geq 0$  and  $(d(u, v) = 0 \text{ iff } u = v)$
- 2)  $d(u, v) = d(v, u)$
- 3)  $d(u, v) \leq d(u, w) + d(w, v)$

} exercise

(This means it's a metric.)

Def<sup>n</sup>. The minimum distance of a code  $\mathcal{C}$

$$\text{is } d(\mathcal{C}) = \min \{ d(u, v) : u, v \in \mathcal{C}, u \neq v \}$$

eg. basic code 000/111

$$d(\mathcal{C}) = 3$$

$$s = 2$$

$$t = 1$$

eg.

code  
= {000  
110  
011  
101}

$$d(\mathcal{C}) = 2$$

$$s = 1$$

$$t = 0$$

Def<sup>n</sup>. A code  $\mathcal{C}$  can

- ① detect  $s$  errors if  $d(\mathcal{C}) \geq s + 1$
- ② correct  $t$  errors if  $d(\mathcal{C}) \geq 2t + 1$

$$s \leq d(\mathcal{C}) - 1$$

$$t \leq \frac{d(\mathcal{C}) - 1}{2}$$
